◆ Results and Discussion
◆ Conclusions
Introduction

- Carbonaceous aerosols accounts for a high portion of PM$_{2.5}$, it includes organic carbon (OC) and element carbon (EC). Most of the EC derives from primary aerosol or incomplete combustion of fossil fuels or biomass; the origin of OC is relatively complex, it can exist in primary contaminant or it can developed from primary organic carbon (POC), which undergoes photochemical reaction and produces secondary organic carbon (SOC). OC and EC account for a high proportion in PM$_{2.5}$, and they have a great impact on environmental quality and human health. This topic is a hotspot in recent years at home or abroad.
Introduction

➢ In recent years, the reports of biomass burning increased a lot, which revealed many large-scale burning incidents in autumn. Although potassium may be useful as a biomass-burning tracer (Andreae, 1983; Echalar et al., 1995), its application is limited by the fact that there are other important sources of this element such as soil and seawater. The monosaccharide levoglucosan released during the pyrolysis of cellulose at temperatures above 300°C, has been proposed as a specific tracer for biomass burning (Simoneit et al., 1999).

➢ Studies have found that, in addition to the effects of factories and motor vehicle emissions in suburban areas, influence of combustion due to exogenous biomass burning on PM$_{2.5}$ cannot be ignored. This research will explore for the first time the effect of biomass burning combustion on the northern suburb of Nanjing.

levoglucosan($\text{C}_6\text{H}_{10}\text{O}_5$)
Experimental Method

» Experiment site
Observation data

Sampling time:
Mar 16th-Apr 15th 2015 Spring
May 25th-Jun 21th 2015 Summer
Oct 06th-Nov 05th 2015 Autumn
Dec 09th-Jan 07th 2015 Winter

Sampling place: Northern Suburbs of Nanjing
Samples: PM$_{2.5}$
Sampling frequency : 12 hours

OC and EC were analyzed by a Sunset Model 4 carbon analyzer with the Thermo optical transmission(TOT) method.

Water soluble ions and three kinds of dehydrated sugar were analyzed by ICS-5000$. 
Using the monitored data OC and EC of four seasons day and night to analyze the level and seasonal variation characters of pollution of OC and EC in the northern industrial area of Nanjing, and using the backward trajectory model and the analysis method of potential source contribution factor (PSCF) to explore the influence of air mass from long distance and regional transportation on PM$_{2.5}$ in the northern suburb of Nanjing.

Using data of water-soluble ions PM$_{2.5}$ monitored day and night in the characteristic months of four seasons to analyze the concentration level, seasonal variation, correlation of all kinds of water-soluble ions and PM$_{2.5}$ composition.

Using the monitoring data of three kinds of sugar in PM$_{2.5}$ to study and explore on the contribution of biomass combustion to PM$_{2.5}$ to northern suburb of Nanjing.
Results and Discussion

Fig 3. The correlation between OC and EC in (a) spring, (b) summer, (c) autumn, (d) winter.
This work uses empirical formula proposed by Turpin et al., to make a quantitative description of SOC:

\[ \text{SOC} = \text{OC} - \text{EC} \times (\text{OC/EC})_{\text{min}} \]

\((\text{OC/EC})_{\text{min}}\) in the equation selected the minimum value during sampling period.

Table 3. Concentration of water-soluble ions in four seasons
Fig 7. The proportion of each ion in (a)spring, (b)summer, (c)autumn, (d)winter.
The correlation between NH$_4^+$ and SO$_4^{2-}$ and NO$_3^-$ is relatively better, and the amount of NH$_4^+$ is relatively high.

When the mole ratio of SO$_4^{2-}$ to NH$_4^+$ is 1:2, it tends to form (NH$_4$)$_2$SO$_4$, and tends to form NH$_4$HSO$_4$ when the molar ratio of SO$_4^{2-}$ to NH$_4^+$ is 1:1.

The proportion of SO$_4^{2-}$ and NH$_4^+$ in the four seasons is generally between 1:1 and 1:2, which is close to 1:2, indicating that in PM$_{2.5}$, sulphate is mainly (NH$_4$)$_2$SO$_4$, and there are also some NH$_4$HSO$_4$. The correlation between NO$_3^-$ and NH$_4^+$ is also good, and tends to form NH$_4$NO$_3$. NH$_4^+$ mainly exists in NH$_4$HSO$_4$, (NH$_4$)$_2$SO$_4$ and NH$_4$NO$_3$.

Fig 8. The relationship between SO$_4^{2-}$, NO$_3^-$ and NH$_4^+$ molar ratio in (a)spring, (b)summer, (c)autumn, (d)winter.
Section 3  Analysis of Biomass Burning

Fig 11. Satellite remote sensing monitoring of biomass burning in mid October 2015.
The type of biomass burned can be judged to some extent with ratio (Levoglucosan/mannosan + galactosan).

The biomass burning is mainly cork when the ratio is 3.4;
The biomass burning is mainly grass when the ratio is 4.7;
The biomass burning is mainly hardwood when the ratio is 12.5;
The biomass burning is mainly crop residue when the ratio is 19.4.

The ratio average in autumn is 20.21 with the minimum 8.97 and the maximum 40.09, means then the biomass burning is mainly crop residue and some grasses and hardwoods in addition.
Fig. 12 Daily variation of levoglucosan and SOC mass concentrations

Fig. 13 The 72h backward trajectories of air mass arriving northern suburbs of Nanjing In October 13th and Fire point data during October 8th to October 10th
Fig. 14 Correlation between potassium, levoglucosan and SOC, OC, EC
Through the receptor tracer method and the Levoglucosan and OC concentration as the tracer to estimate the biomass burning contribution as following:

\[
\text{Biomass burning contribution (\%) } = \frac{\text{(Levoglucosan/OC)}_{\text{sample}}}{\text{(Levoglucosan/OC)}_{\text{source}}} \times 100\%
\]

In the formulation: \((\text{Levoglucosan/OC})_{\text{sample}}\) represents the average ratio of Levoglucosan of this sampling to OC is 1.8%;

\((\text{Levoglucosan/OC})_{\text{source}}\) represents the ratio of Levoglucosan to OC in the biomass burning source spectrum, referenced from 8.3%-average emission factor Levoglucosan/OC in PM\(_{2.5}\) studied by Zhang et al. in combustion emission of grain straw in China;

Autumn’s estimated value is 21.9%, means that the biomass burning during sampling contributes more to OC in the northern suburb of Nanjing, thus it can be seen that the effect of biomass burning on the pollution in northern suburb of Nanjing in the autumn can not be ignored;

During days of 13~16, the average Levoglucosan/OC is 2.5%, the contribution of biomass burning to OC is estimated as 30.1%, which as well confirms that biomass burning is one of the important causes to this pollution.
Conclusion

- The average annual mass concentration of OC is 12.7 μg·m⁻³. The average annual mass concentration of EC is 1.6 μg·m⁻³. The correlation of OC to EC in spring, summer and autumn is relatively good, the correlation between OC and EC is relatively poor in winter. The source of carbonaceous aerosols is more complex, may be affected by a emission source, may be affected by regional polluted air mass, and may also be affected by the photochemical reaction of organic gases.

- The average concentration of water soluble ions in the annual monitoring period is 52.10 μg·m⁻³, the average concentration of water soluble ions in order: winter > summer > autumn > spring; The water soluble ions is mainly SO²⁻, NO₃⁻, NH₄⁺, these ions account for 91.73% of all ions; NH₄⁺, SO₄²⁻ and NO₃⁻ in PM₂.₅ present in the form of NH₄HSO₄, (NH₄)₂SO₄ and NH₄NO₃.

- In autumn, Levoglucosan has good correlation with SOC and OC; The pollution from biomass burning comes mainly from northeast Nanjing, by way of Hebei, Shandong and other places finally reaches the Northern Suburb of Nanjing; The estimated contribution of biomass burning to OC in autumn is 21.7% and 30.1% during the heavily polluted date from October 13 to October 16. This exogenous biomass burning has great influence on the pollution in the North Suburb of Nanjing in autumn.
Thank you
